Multiresolution 3-D Range Segmentation Using Focus Cues

Changhoon Yim, *Member, IEEE*, and Alan C. Bovik, *Fellow, IEEE*

Abstract—This paper describes a novel system for computing a three-dimensional (3-D) range segmentation of an arbitrary visible scene using focus information. The process of range segmentation is divided into three steps: an initial range classification, a surface merging process, and a 3-D multiresolution range segmentation. First, range classification is performed to obtain quantized range estimates. The range classification is performed by analyzing focus cues within a Bayesian estimation framework. A combined energy functional measures the degree of focus and the Gibbs distribution of the class field. The range classification provides an initial range segmentation. Second, a statistical merging process is performed to merge the initial surface segments. This gives a range segmentation at a coarse resolution. Third, 3-D multiresolution range segmentation (3-D MRS) is performed to refine the range segmentation into finer resolutions. The proposed range segmentation method does not require initial depth estimates, it allows the analysis of scenes containing multiple objects, and it provides a rich description of the 3-D structure of a scene.

Index Terms—Bayesian estimation, depth-from-focus, multiresolution range segmentation, 3-D segmentation.

I. INTRODUCTION

THE OBJECTIVE of segmentation is to partition an image or scene into homogeneous regions [1]. In intensity image segmentation, regions are discovered using properties of the image intensity levels [2], [3]. In range image segmentation, regions are computed from range values [2], [4], [5]. The purpose of range image segmentation is to obtain more compact and structured descriptions of surfaces and objects for interpreting range images. In previous range image segmentation methods, it has generally been assumed that the range data is already available from some range finding techniques (e.g., laser range finder, stereo). These range image segmentation methods require the range information as prior knowledge and have generally been limited to applications involving small depth ranges.

Recently much research has been applied to the problem of computing surface depths from focus cues [6]–[14]. Focus

is an attractive source for depth information, since it has no correspondence problem as in stereo [15]. Focus cues can be efficiently used for measuring depth when the initial ranges are not available, for example, in a multimodal active vision system. However, most methods use focus cues for measuring depth at just one image point or for recovering a depth map only for a single object. Little research has been performed on the extended three-dimensional (3-D) reconstruction problem of computing multiple depth ranges or multiple object surfaces using focus cues.

In this paper, we consider simultaneous *range segmentation* and 3-D reconstruction using focus cues. The range segmentation strategy partitions a scene into 3-D regions having different depth ranges, in order to produce a description of the 3-D structure of the objects in the scene, using focus information, without requiring initial depth estimates of the objects.

The proposed range segmentation method unfolds into three steps: an initial range classification process, a merging process, and finally, a 3-D multiresolution range segmentation strategy. Each stage of the algorithm is developed within a Bayesian statistical framework, as summarized next.

The approach taken here computes depth from multiple camera focus positions. The number of focus positions is necessarily limited, and so we first perform a range classification stage to obtain quantized range estimates from focus information. Correct range estimates are difficult to obtain from a finite set of focus positions. In [16], we proposed a range classification algorithm using focus cues in a multiresolution framework. Here we extend this work by casting the problem as a Bayesian estimation problem. The approach is related to the work of several previous authors. Geman *et al.* [17] proposed a statistical framework for partitioning images into homogeneous regions. They employed a Markov random field (MRF) to model image fields. An important feature of the MRF's is that the conditional distribution of a site in the field, given all other sites, is only dependent on its neighbors. By the MRF-Gibbs equivalence property [17]–[19], the probability that the MRF is in a certain state can be calculated using the local energies. It is a Bayesian approach, and it provides a *maximum a posteriori* (MAP) estimate for range classification. The MRF statistical framework has been effectively utilized in many image classification and segmentation methods [17]–[28].

We perform range classification by combining two paradigms: focus cues and Bayesian estimation [29]. A criterion function computed from focus information provides

a basic method for measuring the distribution of ranges in each region of a scene. A Bayesian estimate is obtained by modeling the class field as a Markov random field. An energy functional of the Gibbs distribution of the class field is defined using the MRF-Gibbs equivalence property. To combine these two paradigms, we define a combined energy functional in terms of the energy functional from the criterion function values for focus measure and the energy functional of the Gibbs distribution of the class field. The combined energy functional is minimized by a modified simulated annealing method which yields the range classification.

The range classification provides quantized range estimates. After the range classification stage, we define initial surface segments as connected 3-D surface regions having the same range class values. Hence, the range classification also provides an initial range segmentation.

Once the range classification is performed, it becomes possible to construct cohesive surfaces through a merging process, which combines the initial segments from the range classification result. This gives a 3-D range segmentation at a coarse resolution. In the merging process, we use Gaussian Markov random fields (GMRF's) to model the 3-D vectors of each surface segment. GMRF models have been frequently used for the segmentation of texture images [20], [25], [28], and color images [27].

Finally, we complete and refine the range segmentation taken from the merging process, via a 3-D multiresolution range segmentation (3-D MRS). Multiresolution techniques have been efficiently used for many image segmentation methods [3], [18], [19]. In this final stage, we use multiresolution Markov random fields to model the field of segment indices, range classes, and the 3-D vectors in the surface segments. Using the MRF-Gibbs equivalence relationship, we define energy functionals using segment indices and the 3-D vectors. We also define an energy functional using the criterion function values. A combined energy functional is defined as the weighted summation of these energy functionals, which are constructed over multiple resolutions. The proposed 3-D MRS algorithm first performs range segmentation at the coarsest resolution and proceeds progressively to finer resolutions.

The proposed range segmentation method does not require initial depth estimates, and it provides a rich description of the 3-D structure of a scene.

II. DEPTH FROM FOCUS CUES

For a thin lens, if a point on an object is focused, then the Gaussian lens law holds [6], [9], [12], [15]:

$$\frac{1}{Z} + \frac{1}{p} = \frac{1}{F} \quad (1)$$

where Z is the distance of the point from the lens, p is the image plane distance from the lens, and F is the focal length of the lens.

According to geometric optics, the intensity within the blur circle is approximately a constant. However many factors must be accounted for to get a more accurate modeling of the blurring function. These factors include diffraction effects, sampling errors from digitization, and chromatic aberration

[13], [30]. It has been frequently argued that net effect is effectively described by a two-dimensional (2-D) Gaussian function [7], [11]–[13], [30], [31]:

$$g(x, y) = \frac{1}{2\pi\sigma^2} \exp\left(-\frac{x^2 + y^2}{2\sigma^2}\right) \quad (2)$$

where σ is a spread parameter which controls the amount of defocusing.

Hence, a blurred or defocused image $I_d(x, y)$ can be modeled as the linear convolution of a focused image $I_f(x, y)$ and a Gaussian function $g(x, y)$ [6], [7], [12], [13], [31]:

$$I_d(x, y) = g(x, y) * I_f(x, y). \quad (3)$$

From (3), if an image is defocused, then it is lowpass filtered, and high-frequency components in the image are removed or deemphasized. Thus a defocused image will have a smaller amount of high-frequency content than a focused image of the same scene [6]. Hence, in principle, it should be possible to find the focused image by computing the high-frequency content of multiple images taken at different focus positions.

After the focused image and the corresponding image plane distance p are found, the distance Z can be calculated from (1). To measure the high-frequency contribution, we need a criterion function that is maximized for the focused image.

In (1), the distance Z is a continuous function of the image plane distance for $p > F$. To make the problem feasible, we quantize p in a finite number of steps, meaning that we grab a finite number of images with different image plane distances. Then Z is also quantized into a finite number of steps.

Focus cues yield depth measurements over each image region. The comparison is performed on each image region using different images taken with different image plane distances. By finding the image that maximizes a criterion function, it is possible to estimate the depth of that image region from (1).

Krotkov proposed measuring depth using focus cues at a single image point [9]. Krotkov searches the image plane distance that creates an exact focus by a Fibonacci search strategy. The critical problem of Krotkov's approach is that it can find the depth at only a single image point. This is very limited information, and furthermore, we do not have any prior knowledge about what point at which to measure the depth.

Darrel and Wohn [6] developed a depth from focus method using an image sequence of a scene by varying the image plane distance. They build Gaussian and Laplacian pyramids in the calculation of depth. As a criterion function for focus measure, they use the absolute value of the Laplacian image. After the Laplacian pyramid is generated, the associated absolute-Laplacian criterion function from the multiple images having different image plane distances are compared in order to compute a depth estimate.

Nayar and Nakagawa propose getting a dense depth map from focus [11], [12]. They use several images with different focus positions as in Darrel and Wohn [6]. In their approach, the focal setting is modified by varying the object distance Z instead of image plane distance p of (1). The experimental results include single objects displaying microscopic texture and a very small range of depth. They propose the sum-modified-Laplacian as a criterion function in their experiments

[11], [12]. The peak focus point is estimated by a Gaussian interpolation method. The method appears effective for shape reconstruction over a small depth range, but has not been demonstrated on scenes containing multiple objects or over a large range of depths.

Subbarao and Choi recently proposed a shape-from-focus method that is based on a focused image surface concept [14]. The focused image surface of an object is defined as the surface formed by the set of points at which the object points are focused. In their experiments, they used a sequence of images taken using different image plane distances to reconstruct the shape of an object. This method also assumes a single object surface, and is dependent on the assumption that the images contain sufficient high-frequency content everywhere in the scene to measure the focus accurately. Regions missing the necessary high frequency content result in computed surface errors.

Little research has been performed on the problem of 3-D reconstruction involving multiple objects or multiple depth ranges, using focus cues. Here we consider *range segmentation* using focus cues. The objective of range segmentation is to partition a scene into 3-D regions with different depth ranges to produce a description of the 3-D structure of the scene involving multiple objects, without initial estimates of object depths.

III. CRITERION FUNCTION FOR FOCUS MEASURE

A defocused image is modeled as the convolution of a focused image and a lowpass filter function as in (3). To find the focused image and subsequently measure depth, a criterion function is required to assess the degree of high-frequency content over the spans of images taken with different focus positions.

Krotkov compared several criterion functions experimentally [9]. The functions studied are the Tenengrad (the sum of the gradient magnitude), the sum of the magnitude of Fourier transform, certain types of highpass filtering, histogram entropy, and the sum of modulus difference. Krotkov concluded that of these, the Tenengrad gives the best result.

Now consider the defocusing operation of (3) in the frequency domain (u, v) . Let $I_D(u, v)$, $I_F(u, v)$, and $G(u, v)$ represent the Fourier transforms of $I_d(x, y)$, $I_f(x, y)$, and $g(x, y)$, respectively. Then

$$I_D(u, v) = G(u, v)I_F(u, v). \quad (4)$$

If we model the lowpass filter function for defocusing as a Gaussian function g in (3), then

$$G(u, v) = \exp\left(-\frac{u^2 + v^2}{2}\sigma^2\right). \quad (5)$$

In (4) and (5), as σ is increased, the system is more defocused. Hence, a focused image retains its high-frequency components while a defocused image loses them. An effective criterion function for focus measure should quantify the remaining high-frequency content after the defocusing operation is performed as in (4).

To measure the amount of remaining high-frequency components, we propose to use a highpass function A defined in the frequency domain (u, v) by

$$\begin{aligned} A(u, v) &\equiv 1 - H(u, v) \\ &= 1 - \exp\left(-\frac{u^2 + v^2}{2}\gamma^2\right). \end{aligned} \quad (6)$$

Since the function A has a shape complementary to that of a Gaussian, we call this function the *anti-Gaussian function*.

We argue that the anti-Gaussian function effectively measures the high-frequency content after the defocusing operation is performed. Let $I_a(x, y)$ be the anti-Gaussian filtered image for a defocused image $I_d(x, y)$. Then

$$I_a(x, y) = a(x, y) * I_d(x, y) \quad (7)$$

where $a(x, y)$ is the inverse Fourier transform of $A(u, v)$. Note that we propose (6) as a method for capturing high frequencies, *not* as a mechanism to strictly invert the blur. That is, we do not seek that $1 - H(u, v) \approx 1/G(u, v)$.

A highpass filtered image can be computed as the difference between the original image and a lowpass filtered version of the image. Multiplying the original image by an amplification factor κ and then subtracting the lowpass image from it yields a *high-boost filter* [1]:

$$\text{High boost} = (\kappa)(\text{Original}) - \text{Lowpass}. \quad (8)$$

The general process of subtracting a blurred image from an original, as expressed in (8), is called *unsharp masking* [1]. The anti-Gaussian filter implements the highpass filter by subtracting the Gaussian filtered version of the image from the original image. Hence, the anti-Gaussian filter is a kind of unsharp masking where the lowpass filter is the Gaussian filter and the amplification factor κ is 1 in (8). High frequencies are emphasized at the expense of lower frequencies, but in a controlled manner.

For a focus measure, we propose to use a spatial summation of the squared anti-Gaussian filtered images. We call this function *sum-square-anti-Gaussian* (SSAG) function. The SSAG function for measuring the degree of focus of a region $\mathcal{A}$ in an image is defined as

$$S(\mathcal{A}) = \sum_{(i,j) \in \mathcal{A}} (I_a(i, j))^2 \quad \text{for } |I_a(i, j)| > T_h \quad (9)$$

where T_h is a threshold value. This threshold operation is performed to reduce noise effects and is also performed in other criterion functions (e.g., Tenengrad [9]).

When a region contains adequate high-frequency content (e.g., edge or texture regions), the focus measure function effectively assesses the amount of high-frequency content in images taken at different focus positions. In such cases, the criterion function becomes large and yields reliable range estimates. However, when a region contains a small amount of high-frequency content, it is difficult to compare the high-frequency content between images at different focus positions, due to noise effects. This effect becomes more severe as the region size is reduced.

IV. RANGE CLASSIFICATION

A. Range Classification: Problem

Assume that we take K images $I_1, I_2, \dots, I_K$ with different image plane distances. The object distance from the lens can be calculated from the image plane distance by the Gaussian lens law (1). In practical situations, we do not obtain depth by (1) because we do not know the real image plane distance accurately. It is preferable to build a look-up table for depth corresponding to each image plane location. If we take K images with different image plane distances, we obtain the corresponding K depths experimentally. To compute range from focus, we obtain the index yielding the best among the K images, instead of finding the range directly. We call this index the *range class value*. We can obtain quantized depth or range from the range class value.

Now consider a region $\mathcal{A}$ in the set of images. The process of range classification maps a region $\mathcal{A}$ to one of the range class values in $\{1, 2, \dots, K\}$. Let $\mathcal{Z}(\mathcal{A})$ and $\hat{\mathcal{Z}}(\mathcal{A})$ represent the real depth and the estimated depth value of region $\mathcal{A}$, respectively.

Let $\mathcal{R}(\mathcal{A})$ represent the *range class value* of region $\mathcal{A}$. Then $\mathcal{R} \in \{1, 2, \dots, K\}$ and $\mathcal{R}(\mathcal{A}) = m \Rightarrow \hat{\mathcal{Z}}(\mathcal{A}) = Z_m$ in range classification. In other words, if a region $\mathcal{A}$ has a range class value m from the range classification, then the region $\mathcal{A}$ has the estimated depth value Z_m . Hence, depth is quantized in the range classification process.

Let $f_i(\mathcal{A})$ denote the criterion function values of the i th image. *Range quantization* using focus cues is computed as

$$m = \arg \max_i f_i(\mathcal{A}) \Rightarrow \mathcal{R}(\mathcal{A}) = m. \quad (10)$$

Thus, the range class value of region $\mathcal{A}$ is found by comparing the criterion function values $f_i(\mathcal{A})$, for $i = 1, 2, \dots, K$, thus providing an initial range classification.

Region $\mathcal{A}$ is defined to be *focus measurable*, if it satisfies

$$m = \arg \max_i f_i(\mathcal{A}) \Leftrightarrow \mathcal{R}(\mathcal{A}) = m. \quad (11)$$

If region $\mathcal{A}$ is focus measurable, then we can find the correct range class value of $\mathcal{A}$ just using the criterion function values, i.e., using focus cues, and there is no difficulty obtaining range classification using focus cues. In this case, we can simply

perform range classification from the range quantization using focus cues as in (10).

If a region does not contain enough high-frequency content, then this region may not be focus measurable. This case typically occurs at homogeneous regions in images. In practice, many regions in the scene are not focus measurable.

Now we show some examples of range classification through range quantization using focus cues. Range quantization using focus cues is defined in (10). In these examples, we collect eight images defined by eight different focus positions, i.e., with different image plane distances. These images are labeled as $I_1, I_2, \dots, I_8$. Fig. 1 shows two of these images with different focus positions.

We perform range quantization using different criterion functions in different resolutions, i.e., in different region sizes. We show range quantization examples using two kinds of criterion functions for focus measure: Tenengrad and SSAG. We perform range quantization in several region sizes. Among them, we show range quantization results in two region sizes: 32×32 and 16×16 . Fig. 2(a) and (b) show the range quantization results in regions of 32×32 pixel blocks using Tenengrad and SSAG, respectively. Fig. 2(c) and (d) show the range quantization results in regions of 16×16 pixel blocks using Tenengrad and SSAG, respectively. In Fig. 2, each region represented by each distinct gray level corresponds to one range class.

In these results, we can see that no criterion function for focus measure gives perfect range quantization results at any resolution. As the region size becomes larger, we obtain more robust range quantization result while losing resolution. On the other hand, as the region size becomes smaller, errors in range quantization increase significantly.

From these examples, we conclude that there are limitations on range classification through range quantization just using focus cues. We need a new approach to solve this problem. We propose a statistical approach, which uses the posterior distribution of range classes. It employs an MRF model to achieve range classification.

B. Statistical Model for Range Classification

Let F_i represent a field of the focus criterion function values for the i th image. Let X represent a field of range classes. Then

Fig. 2. Range quantization using different criterion functions in different region sizes. (a) Tenengrad (32×32). (b) SSAG (32×32). (c) Tenengrad (16×16). (d) SSAG (16×16).

points or sites in X take values in the set $\{1, 2, \dots, K\}$ where K is the number of classes. This K value corresponds to the number of images with different focus positions.

We use an MRF to model X . For an MRF, the conditional distribution of a site in the field given all other sites is only dependent on its neighbors. In order to define an MRF, the neighborhood system must first be defined. Let $\mathcal{G}_s$ be the set of neighbors of site s , and $\mathcal{G}_{(i,j)}$ be the set of neighbors of a site with coordinate (i, j) .

We will use a four-neighborhood system in which the neighbors of coordinate (i, j) are given by

$$\mathcal{G}_{(i,j)} = \{(i-1, j), (i+1, j), (i, j-1), (i, j+1)\}.$$

The four-neighborhood system is also known as the first-order or nearest-neighbor system [17]. A *clique* C is a subset of sites in S such that if s and r are two points in C , then s and r are neighbors [18], [17].

We assume a common state space $\Lambda = \{1, 2, \dots, K\}$ so that $X_s \in \Lambda$ for all s . Let Ω be the set of all possible configurations. A *Gibbs distribution* is a probability measure π on Ω with the following representation:

$$\pi(\omega) = \frac{1}{N} e^{-U(\omega)/T} \quad (12)$$

where N is a normalizing constant, and T is the *temperature* [17], [19]. U is called the *energy function*.

The energy function U is defined as [17], [18]:

$$U(\omega) = \sum_{C \in \mathcal{C}} V_C(\omega) \quad (13)$$

where $\mathcal{C}$ denotes the set of cliques for $\mathcal{G}$. V_C is a function on Ω with the property that $V_C(\omega)$ depends only on those coordinates x_s of ω for which $s \in C$. Such a family $\{V_C, C \in \mathcal{C}\}$ is called a *potential*.

The MRF-Gibbs equivalence property [17]–[19] provides a simple and practical way of specifying MRF's. The probability that the MRF is in a certain state can be calculated using the local energies. By the MRF-Gibbs equivalence, if $\pi(x)$ is formulated as a Gibbs distribution, then X will have the properties of an MRF. Since we use the four-neighborhood system, the only cliques in the energy function for $\pi(x)$ are pairs of horizontally and vertically adjacent sites. The potentials, $V_c = 0$ unless $C = \{r, s\}$ is a clique, in which case

$$V_C(x_s) = \begin{cases} 0, & x_s = x_r \\ 1, & x_s \neq x_r. \end{cases} \quad (14)$$

Then

$$U(x_s) = \frac{1}{N_U} \sum_{C \in \mathcal{C}} V_C(x_s) \quad (15)$$

where N_U is a constant. We set $N_U = \text{card}(\mathcal{G}_s)$. In the four-neighborhood system, $\text{card}(\mathcal{G}_s) = 4$. Then the energy functional $U(x_s)$ is normalized so that $0 \leq U(x_s) \leq 1$. $U(x)$

is the energy functional defined by the MRF modeling of X . This measures the similarity of range classes across the image space.

Let $f_{s,x}$ represent the criterion function value of site s , assuming range class x . From the criterion function values, we can find the most likely range class value of site s as

$$x_s^* = \arg \max_x f_{s,x}. \quad (16)$$

Equation (16) represents the range quantization using focus cues as in (10). This is the basic rule for measuring ranges using focus cues. Let f_s^* be the maximum criterion function values of site s , i.e.,

$$f_s^* = \max_x f_{s,x}.$$

Then f_s^* is the desired criterion function value satisfying (16).

We define an energy functional $\Gamma(x)$ by the criterion function values

$$\Gamma(x_s) = \frac{|f_s^* - f_{s,x}|}{f_s^*}. \quad (17)$$

The energy functional $\Gamma(x_s)$ is normalized so that $0 \leq \Gamma(x_s) \leq 1$. This functional has the minimum value 0 when $f_s^* = f_{s,x}$, i.e., x is the class value that has the maximum value in the criterion function value at site s . $\Gamma(x)$ is the energy functional defined by the criterion function values. This measures the degree of closeness to good focus.

From the energy functionals $U(x), \Gamma(x)$ in (15), (17), we define the *combined energy functional* $E(x)$:

$$E(x) = \lambda \Gamma(x) + (1 - \lambda) U(x) \quad (18)$$

where λ is a constant between zero and one. Then $E(x)$ is also normalized so that $0 \leq E(x) \leq 1$. The combined energy functional $E(x)$ has information both from the class field defined by the MRF and from the field of criterion function values.

The λ value in (18) determines the weight on the energy functionals $\Gamma(x)$ and $U(x)$. As the λ value is increased, there will be more weight on the energy functional $\Gamma(x)$ and less weight on the energy functional $U(x)$, and vice versa. As explained in Section III, larger criterion function values are more reliable data for measuring focus. Using this information, we assign the λ value in an adaptive fashion. We assign the value of λ of site s based on the maximum criterion function value f_s^* of site s as (19).

$$\lambda = \begin{cases} 1, & f_s^* \geq T_f \\ \frac{f_s^*}{T_f}, & f_s^* < T_f \end{cases} \quad (19)$$

where T_f is a threshold. The T_f value is chosen large enough such that if the maximum criterion function value f_s^* of site s is greater than T_f , then the range quantization by (16) provides a reliable range classification. However, if T_f value is chosen too large, then the λ values will become small, and the combined energy functional E is mainly dependent on U in (18).

The range classification is obtained by minimizing $E(\omega)$ over all configurations $\omega \in \Omega$. It is a nonlinear optimization problem that can be solved with relative efficiency using a modified simulated annealing method.

C. Modified Simulated Annealing

Simulated annealing is a kind of stochastic relaxation method for minimizing an energy function $E(x)$ as a function of the state x [18]. It works by generating a chain of these states. The minimum of $E(x)$ is found by allowing the temperature T to fall slowly as the chain is generated.

Standard simulated annealing algorithm begins in an arbitrary state and then successively generates candidate state transitions at random [32]. Given the state $X(t)$ at time t , one randomly chooses another configuration η and computes the energy change $\Delta E = E(\eta) - E(X(t))$. A transition is accepted with the following probability:

$$P(X(t+1) = \eta | X(t), \eta) = \begin{cases} 1, & \text{if } \Delta E < 0 \\ \exp(-\Delta E/T), & \text{otherwise.} \end{cases}$$

As the temperature T is decreased, the probability of transition is decreased.

At time t , the state at site s is a random variable $X(t)$ with values in Λ_s . For generating samples, we use the Gibbs sampler [17]. In a Gibbs sampler, only one site undergoes a possible change at each epoch, so that $X(t-1)$ and $X(t)$ can differ in at most one coordinate. Let $n_1, n_2, \dots$ be the sequence in which the sites are visited for replacement. The sequence (n_t) that is actually used is the one corresponding to a raster scan [17]. As a result, all sites are visited at each iteration.

Instead of visiting all sites as in standard simulated annealing, only selected sites are visited at each iteration. In doing so, we define *stable* sites and *unstable*. Only unstable sites are visited for replacement at each iteration.

In the range classification algorithm, we define two types of stable sites. First, if the maximum value of the criterion function value of site s is greater than the threshold T_f in (19), i.e., $f_s^* > T_f$, then this site is deemed stable. Second, if a site s has the same class value as all of its neighbors, i.e., $x_s = x_r$ for all $r \in \mathcal{G}_s$, then the site s is also regarded as stable.

The first case uses the criterion function values. As explained in Section III, large criterion function values are reliable data for measuring focus. The second case uses the MRF model of field X . If the class values of neighbors of site s are the same, then the energy $U(x_s)$ is minimum only when x_s is the same as these values. Assume that $x_r = x_t$ for all $r, t \in \mathcal{G}_s$. Then

$$U(x_s) = \begin{cases} 0, & x_s = x_r \\ 1, & x_s \neq x_r. \end{cases}$$

If a site is not stable, then it is defined to be unstable.

In the modified simulated annealing method, only unstable sites are visited at each iteration, and unstable sites are updated after each iteration. If the number of unstable sites is decreased at each iteration, the amount of computation for the simulated annealing process is greatly reduced.

The initial state supplied to the simulated annealing process is often of critical importance [18]. In standard simulated annealing, the initial state is frequently assigned at random. In modified simulated annealing for range classification, the initial state of the classes of sites is determined by (16).

V. MERGING PROCESS

The range classification provides an initial range segmentation. After the range classification is performed, a merging process is performed to create surface segments, thus yielding a 3-D range segmentation at a coarse resolution.

In the merging process, we use 3-D vectors in a world coordinate system (WCS). The 3-D vectors in the WCS are obtained using the 3-D mapping process given in Section V-B.

For the merging process, we use a GMRF to model the field of 3-D vectors of a segment. The approach taken is similar to those taken for the successful segmentation of texture images [20], [25], [28] and color images [27].

A. Range Interpolation

The range class values from the range classification process provide quantized range estimates. In the merging process, we use interpolated range values instead of quantized range values to attain greater range resolution.

To obtain interpolated range values, we require an appropriate interpolation operation. Nayar and Nakagawa use Gaussian functions to interpolate the criterion function values [12]. They express the criterion function using the Gaussian model. The Gaussian interpolation method [12] uses only three criterion function values, f_{m-1} , f_m , and f_{m+1} , when I_m is the best focused image. Subbarao and Choi interpolated range values by quadratic and cubic polynomial fitting [14]. They also use three criterion function values. For the interpolation using three criterion function values, we should first obtain the index m for best focusing, i.e., the range class value.

Here, we use cubic spline interpolation to interpolate the criterion function values. First, the cubic spline interpolation is performed to interpolate the criterion function values. Then the location that has the maximum value among the interpolated criterion function values gives the interpolated range value. This method uses all the criterion function values for the range interpolation. We can apply this method even though the range class value is not available.

In range interpolation, if a site s is not focus measurable, we assign the average value of the range values of the neighborhood having the same range class value.

B. 3-D Mapping from Ranges

Let (x_w, y_w, z_w) represent the coordinates of (3-D) vectors with respect to the center point of the camera position in a world coordinate system (WCS), and let (i, j) represent row and column coordinates in the sequence of images. Let (x_p, y_p) represent the image coordinates with respect to the center point in the image plane of the camera. Let N_x and N_y represent the number of pixels in the images in the horizontal and vertical directions, respectively, and b_x and b_y be the image plane size of the camera in the horizontal and vertical directions, respectively. Then the relationship between (x_p, y_p) and (i, j) is

$$\frac{x_p}{b_x} = \frac{j - N_y/2}{N_x} \quad (20)$$

$$\frac{y_p}{b_y} = \frac{-(i - N_x/2)}{N_y}. \quad (21)$$

There is a minus sign in (21) because the row coordinate values i in the images are indexed from top to bottom. The relationship between (x_w, y_w, z_w) and (x_p, y_p) is

$$\frac{x_w}{x_p} = \frac{y_w}{y_p} = \frac{z_w}{F} \quad (22)$$

where F is the focal length of the camera.

We have estimates of the object distance z_w given the image plane distance as explained in Section II. The z_w values can be preestimated and stored as a look-up table for the range values.

By (20)–(22), the mapping functions from (i, j) and z_w to (x_w, y_w) are

$$x_w = x_p \frac{z_w}{F} = \frac{z_w b_x (j - N_x/2)}{F N_x} \quad (23)$$

$$y_w = y_p \frac{z_w}{F} = \frac{-z_w b_y (i - N_y/2)}{F N_y}. \quad (24)$$

C. Statistical Model for Merging Process

GMRF's are a special case of Markov random fields [27], [33]. GMRF models have been extensively used for the segmentation of texture images [20], [25], [28]. Recently, Panjwani and Healey used the GMRF model for the segmentation of textured color images [27].

In this paper, a criterion for the merging process is developed as a similarity measure between segments using the GMRF model. The GMRF is defined from the conditional probability density function of each segment.

Let $\mathbf{w}(i, j) = [w_1(i, j) \ w_2(i, j) \ w_3(i, j)]^t$ denote a 3-D vector representing a location in a WCS at image coordinate (i, j) . In $\mathbf{w}$, w_1 , w_2 , and w_3 correspond to x_w , y_w , and z_w , respectively, in the WCS of Section V-B. Let W_S denote the field of $\mathbf{w}$ in segment S . If $\mathbf{w}(i, j) \in W_S$, then $\mathbf{w}(i, j)$ represents the 3-D vector at (i, j) in segment S . We model W_S as a GMRF.

Let $\mathbf{w}(i, j)$ or $\mathbf{w}_r$ represent a 3-D vector in segment S . Let $\mu_{1,S}$, $\mu_{2,S}$, and $\mu_{3,S}$ denote the mean of $w_1(i, j)$, $w_2(i, j)$, and $w_3(i, j)$ in segment S , respectively.

$P(\mathbf{w}(i, j)|S)$ represents the conditional probability density function of $\mathbf{w}(i, j)$ in segment S , and it has the Gaussian distribution

$$P(\mathbf{w}(i, j)|S) = \frac{1}{(8\pi^3|V_S|)^{1/2}} \exp \left\{ -\frac{1}{2} \mathbf{e}(i, j) V_S^{-1} (\mathbf{e}(i, j))^t \right\} \quad (25)$$

where $\mathbf{e}(i, j) = [e_1(i, j) \ e_2(i, j) \ e_3(i, j)]^t$ is a zero mean Gaussian random vector and where V_S denotes the correlation matrix of $\mathbf{e}(i, j)$ in segment S . Each component $e_k(i, j)$ of $\mathbf{e}(i, j)$, for $k = 1, 2, 3$, is defined as

$$e_k(i, j) = (w_k(i, j) - \mu_{k,S}) - \sum_{(m,n) \in \mathcal{G}_{(i,j)}^S} \alpha_k(m, n) \cdot (w_k(m, n) - \mu_{k,S}) \quad (26)$$

where the α_k 's are the model parameters and $\mathcal{G}_{(i,j)}^S \equiv \mathcal{G}_{(i,j)} \cap S$, where $\mathcal{G}_{(i,j)}$ denotes the set of neighbors of coordinate

(i, j) . If we use the four-neighborhood system, then $\mathcal{G}_{(i,j)} = \{(i, j-1), (i, j+1), (i-1, j), (i+1, j)\}$. The α_k 's in (26) are the model parameters representing the weights on the neighborhood information of the 3-D vectors in the x, y , and z directions, respectively. We assume the same weights on the neighborhood information of the 3-D vectors in the x, y , and z directions. Hence, we set $\alpha = \alpha_1 = \alpha_2 = \alpha_3$ where

$$\alpha(m, n) = \frac{1}{\text{card}(\mathcal{G}_{(i,j)}^S)} \quad \text{for } (m, n) \in \mathcal{G}_{(i,j)}^S. \quad (27)$$

Let $V_{k,S}$ be the expected value of e_k^2 in segment S for $k = 1, 2, 3$. Then

$$V_S = \begin{bmatrix} V_{1,S} & 0 & 0 \\ 0 & V_{2,S} & 0 \\ 0 & 0 & V_{3,S} \end{bmatrix}. \quad (28)$$

Note that V_S is a diagonal matrix. For the GMRF model, let Θ_S be the vector of the $\mu_{1,S}, \mu_{2,S}, \mu_{3,S}$ and the $\alpha_1, \alpha_2, \alpha_3$ parameters in segment S .

D. Merging Criteria and Algorithm

The criterion that we use for merging is based on the pseudolikelihood and bears resemblance to the approach used by Panjwani and Healey for color texture image segmentation [27].

For a segment S modeled by a GMRF, the pseudolikelihood of segment S is given by

$$P_{ps}(S|\Theta_S, V_S) = \prod_{(i,j) \in S} \frac{1}{(8\pi^3|V_S|)^{1/2}} \cdot \exp \left\{ -\frac{1}{2} \mathbf{e}(i, j) V_S^{-1} (\mathbf{e}(i, j))^t \right\}. \quad (29)$$

The function $P_{ps}(S|\Theta_S, V_S)$ is the product of the conditional probability densities of the 3-D vectors $\mathbf{w}$ in segment S .

Let $S_1, S_2, \dots, S_K$ represent the initial surface segments from the range classification. Let S_k and S_l be two adjacent segments, and let S_M be a segment obtained by merging S_k and S_l . We model W_{S_k}, W_{S_l} , and W_{S_M} by GMRF's with parameter vectors $\Theta_{S_k}, \Theta_{S_l}$, and Θ_{S_M} , respectively. Let $R_{ps}(k, l)$ be the ratio of the pseudolikelihood before the merge and the pseudolikelihood after the merge. Then

$$R_{ps}(k, l) = \frac{\prod_{r=1,2,\dots,K} P_{ps}(S_r|\Theta_{S_r}, V_{S_r})}{P_{ps}(S_M|\Theta_{S_M}, V_{S_M}) \prod_{r \neq k,l} P_{ps}(S_r|\Theta_{S_r}, V_{S_r})}. \quad (30)$$

This equation is simplified to

$$R_{ps}(k, l) = \frac{P_{ps}(S_k|\Theta_{S_k}, V_{S_k}) P_{ps}(S_l|\Theta_{S_l}, V_{S_l})}{P_{ps}(S_M|\Theta_{S_M}, V_{S_M})}. \quad (31)$$

If the value of $R_{ps}(k, l)$ is near one, this indicates that S_k and S_l have similar 3-D vectors $\mathbf{w}$.

For the convenience of computation, a function $h(k, l)$ is defined as

$$h(k, l) = \ln(R_{ps}(k, l)). \quad (32)$$

Since V_S is a diagonal matrix, $h(k, l)$ can be simplified [27] to

$$h(k, l) = \frac{N_k + N_l}{2} \ln(|V_{S_M}|) - \frac{N_k}{2} \ln(|V_{S_k}|) - \frac{N_l}{2} \ln(|V_{S_l}|) \quad (33)$$

where $|V_S|$ represents the determinant of V_S , and N_k and N_l represent the cardinality of segments S_k and S_l , respectively.

The merging criteria that we use are as follows. First, segments for merging should be spatially adjacent. Second, segments for merging should be adjacent in their range class values. Third, the log of the pseudolikelihood ratio for merging should be less than a threshold. The segment pairs satisfying all these three criteria are to be merged.

The conditions for the first and second criteria can be easily obtained from the coordinate values and the range class values of segments. The condition for the third criterion is obtained by the GMRF model of each segment. The pseudolikelihood ratio represents the similarity of 3-D vectors between segments.

The merging algorithm can be summarized as follows.

- 1) Find and number initial segments.
- 2) Find the cardinality of each segment.
- 3) Calculate each component of $\mathbf{e}(i, j)$ in each segment by (26), and V_S of each segment by (28).
- 4) For each pair of segments, check whether it satisfies the first and second criterion.
- 5) For each segment pair that is found in 4), calculate the log of the pseudolikelihood ratio by (33), and determine whether it is to be merged by the third criterion.
- 6) Perform the merging for each segment pair to be merged.

In 1), each segment is defined as a connected region in images having the same range class values. The order of numbering is arbitrary. We numbered the segments from the segment with lower range class values to the segment with higher range class values.

VI. 3-D MULTIREOLUTION RANGE SEGMENTATION

The merging process provides a 3-D range segmentation at the coarsest resolution. To refine the range segmentation into finer resolutions, we perform a 3-D MRS.

For 3-D MRS, we use multiresolution Markov random fields to model the field of surface segment indices, range classes and the 3-D vectors in segments. Using the MRF-Gibbs equivalence, we define energy functionals using segment indices and the 3-D vectors. We also define an energy functional using the criterion function values. A combined energy functional is defined as the weighted summation of these energy functions. The combined energy functional includes information from the criterion function values, the segment indices and the 3-D vectors. To create a multiresolution framework, the energy functionals are defined over multiple resolutions. Three-dimensional range segmentation is performed over multiple resolutions by a coarse-to-fine strategy.

A. Statistical Model for 3-D MRS

The 3-D MRS algorithm begins the process of range segmentation at the coarsest resolution and uses the result as

an initial condition for range segmentation at the next finer resolution. The initial state of the 3-D MRS is obtained by the merging process performed at the coarsest resolution.

In a multiresolution framework, each resolution corresponds to a level in a quad tree. A lattice point at one resolution corresponds to four points at the next finer resolution. The mapping from pixel coordinates at the (l) th resolution level to points at the previous coarser $(l+1)$ th level can be formally written as [18]

$$D((i, j)) = (\lfloor i/2 \rfloor, \lfloor j/2 \rfloor) \quad (34)$$

where $\lfloor \cdot \rfloor$ denotes the floor function. Also, $D^k(\cdot)$ will denote the composition of the function $D(\cdot)$ with itself k times.

$X^{(l)}$ denotes the field of range classes at resolution level (l) . Sites in $X^{(l)}$ take values in the set $\{1, 2, \dots, K\}$ where K is the number of range classes. $Y^{(l)}$ denotes the field of segment indices at resolution level (l) . If there are M segments, sites in $Y^{(l)}$ take values in the set $\{1, 2, \dots, M\}$. The number of segments M is obtained after the merging process.

$F_i^{(l)}$ denotes the field of the criterion function values of the i th image at resolution level (l) . $f_{s,x}^{(l)}$ represents the criterion function value of the range class value x of site s at level (l) . Then

$$f_{s,x}^{(l)} = \sum_{r \in D^{-1}(s)} f_{r,x}^{(l-1)} \quad (35)$$

where $D^{-1}(s)$ is the set of sites at the next finer resolution which map to s . This means that the criterion function value at level (l) can be represented as the summation of the criterion function value at level $(l-1)$.

Let $\mathbf{w}_s^{(l)} = [w_{1,s}^{(l)} \ w_{2,s}^{(l)} \ w_{3,s}^{(l)}]^t$ denote the 3-D vector in WCS of site s at level (l) . The value of the 3-D vector $\mathbf{w}_s^{(l)}$ depends on the value of $y_s^{(l)}$, and it can be represented as a function of $y_s^{(l)}$:

$$\mathbf{w}_s^{(l)} \equiv \mathbf{w}(y_s^{(l)}).$$

In $\mathbf{w}_s^{(l)}$, $w_{3,s}^{(l)}$ denotes the object distance or the depth range. Let $\mathcal{Z}(y_s^{(l)})$ represent the object distance of site s with segment index value $y_s^{(l)}$. Then

$$w_{3,s}^{(l)} \equiv \mathcal{Z}(y_s^{(l)}).$$

Here $w_{1,s}^{(l)}$, $w_{2,s}^{(l)}$, and $w_{3,s}^{(l)}$ correspond to x_w , y_w , and z_w , respectively, in the WCS in Section V-B. Hence $w_{1,s}^{(l)}$ and $w_{2,s}^{(l)}$ can be calculated from $w_{3,s}^{(l)}$ and the coordinate value of site s by the 3-D mapping method. Let $W^{(l)}$ denote the field of the 3-D vectors $\mathbf{w}^{(l)}$.

We use multiresolution MRF's to model $X^{(l)}$, $Y^{(l)}$, and $W^{(l)}$ at each level (l) . We define energy functionals under the Bayesian framework at each level.

From the criterion function values, we can find the range class value $x_s^{(l)}$ of site s as

$$x_s^{(l)} = \arg \max_x f_{s,x}^{(l)} \quad (36)$$

Let $f_s^{(l),*}$ be the maximum criterion function value of site s at level (l) , i.e.,

$$f_s^{(l),*} = \max_x f_{s,x}^{(l)}. \quad (37)$$

The energy functional $\Gamma^{(l)}(x_s)$ of site s from the criterion function values at level (l) is defined as

$$\Gamma^{(l)}(x_s) = \frac{|f_s^{(l),*} - f_{s,x}^{(l)}|}{f_s^{(l),*}} \quad (38)$$

where $f_s^{(l),*}$ in the denominator is for normalization. Then $\Gamma^{(l)}(x_s)$ is normalized so that $0 \leq \Gamma^{(l)}(x_s) \leq 1$.

By the MRF-Gibbs equivalence, the probability distribution of field $Y^{(l)}$ is formulated as a Gibbs distribution. Let $V_C^{(l)}(y_s)$ represent the potential functional of site s at level (l) . The potentials, $V_C^{(l)} = 0$ unless $C = \{r, s\}$ is a clique, in which case

$$V_C^{(l)}(y_s) = \begin{cases} 0, & y_s = y_r \\ 1, & y_s \neq y_r. \end{cases} \quad (39)$$

The energy functional $U^{(l)}(y_s)$ defined by the MRF modeling of $Y^{(l)}$ is

$$U^{(l)}(y_s) = \frac{1}{N_U^{(l)}} \sum_{C \in \mathcal{C}} V_C^{(l)}(y_s) \quad (40)$$

where $N_U^{(l)}$ is a constant at level (l) . We set $N_U^{(l)} = N_U = \text{card}(\mathcal{G}_s)$. Then $U^{(l)}(y_s)$ is normalized so that $0 \leq U^{(l)}(y_s) \leq 1$.

Let $P_C^{(l)}(\mathbf{w}_s)$ represent the potential functional of $\mathbf{w}_s$ at level (l) . The potentials $P_C^{(l)} = 0$ unless $C = \{s, r\}$ is a clique, in which case,

$$P_C^{(l)}(\mathbf{w}_s) = \|\mathbf{w}_s^{(l)} - \mathbf{w}_r^{(l)}\| \quad (41)$$

where $\|\cdot\|$ represents the Euclidean norm. Hence, $P_C^{(l)}(\mathbf{w}_s)$ is a Euclidean distance between site s and site r where $\{s, r\}$ is a clique.

The energy functional $Q^{(l)}(\mathbf{w}_s)$ from the 3-D vector $\mathbf{w}_s$ by the MRF modeling of $W^{(l)}$ at level (l) is defined as

$$Q^{(l)}(\mathbf{w}_s) = \frac{1}{N_{Q,s}^{(l)}} \sum_{C \in \mathcal{C}} P_C^{(l)}(\mathbf{w}_s) \quad (42)$$

where $N_{Q,s}^{(l)}$ is a normalization factor. We set $N_{Q,s}^{(l)}$ as

$$N_{Q,s}^{(l)} = \sum_{r \in \mathcal{G}_s} \sum_{C \in \mathcal{C}} P_C^{(l)}(\mathbf{w}_r). \quad (43)$$

Then, $Q^{(l)}(\mathbf{w}_s)$ is also normalized so that $0 \leq Q^{(l)}(\mathbf{w}_s) \leq 1$.

The combined energy functional $E^{(l)}(x, y, \mathbf{w})$ at level (l) is defined as

$$E^{(l)}(x, y, \mathbf{w}) = \lambda_1^{(l)} \Gamma^{(l)}(x) + \lambda_2^{(l)} U^{(l)}(y) + \lambda_3^{(l)} Q^{(l)}(\mathbf{w}) \quad (44)$$

where $\lambda_1^{(l)}$, $\lambda_2^{(l)}$, and $\lambda_3^{(l)}$ are constants between zero and one with

$$\lambda_1^{(l)} + \lambda_2^{(l)} + \lambda_3^{(l)} = 1. \quad (45)$$

Then $E^{(l)}(x, y, \mathbf{w})$ is also normalized so that $0 \leq E^{(l)}(x, y, \mathbf{w}) \leq 1$.

The $\lambda_k^{(l)}$ (for $k = 1, 2, 3$) values in (44) determine the weight on the energy functionals $\Gamma^{(l)}(x)$, $U^{(l)}(y)$ and $Q^{(l)}(\mathbf{w})$. As the $\lambda_1^{(l)}$ value becomes larger, there will be more weight on the energy functional $\Gamma^{(l)}(x)$ while less weight on other energy functionals. $\Gamma^{(l)}(x)$ is the energy functional defined by the criterion function values measuring the degree of closeness to good focus. As explained in Section III, larger criterion

function values are more reliable data for measuring focus. The $\lambda_k^{(l)}$ values are selected adaptively using the criterion function value information. We assign the value of $\lambda_1^{(l)}$ of site s based on the maximum criterion function value $f_s^{(l),*}$ of site s :

$$\lambda_1^{(l)} = \begin{cases} 1, & f_s^{(l),*} \geq T_f^{(l)} \\ \frac{f_s^{(l),*}}{T_f^{(l)}}, & f_s^{(l),*} < T_f^{(l)} \end{cases} \quad (46)$$

where $T_f^{(l)}$ is a threshold at level (l) .

The threshold value $T_f^{(l)}$ is determined to be proportional to the number of pixels in a block at level (l) . Since the size of a block at level (l) is $2^l \times 2^l$, the number of pixels in a block at level (l) is $2^l \cdot 2^l = 2^{2l}$. The threshold value $T_f^{(l)}$ at level (l) can be represented in terms of the threshold value $T_f^{(0)}$ at level (0) :

$$T_f^{(l)} = T_f^{(0)} \cdot 2^{2l}. \quad (47)$$

Let

$$\lambda_2^{(l)} = \eta(1 - \lambda_1^{(l)})$$

where η is a constant between zero and one. Then

$$\lambda_3^{(l)} = (1 - \eta)(1 - \lambda_1^{(l)}).$$

The value η determines the weight on the energy functionals $U^{(l)}(y)$ and $Q^{(l)}(w)$, and this value can be assigned arbitrarily. In experiments, we set $\eta = \frac{1}{3}$. This means that we assign more weight on the energy functional $Q^{(l)}(w)$ from the 3-D vectors than on the energy functional $U^{(l)}(y)$ from the segment indices.

B. 3-D MRS Algorithm

The optimization criteria we use for finding the best range segmentation at level (l) is

$$(\hat{x}^{(l)}, \hat{y}^{(l)}) = \arg \min_{x,y} \{E^{(l)}(x,y,w)\}. \quad (48)$$

We call (x_s, y_s) the state of site s . The state represents the range class value and segment index of site s . We assume a common state space $\Lambda = \{(x,y): x \in \{1,2,\dots,K\}, y \in \{1,2,\dots,M\}\}$ so that $(x_s, y_s) \in \Lambda$ for all s . Let $\Omega^{(l)}$ be the set of all possible configurations at level (l) . The range segmentation at level (l) is obtained by minimizing $E^{(l)}(w)$ over all configurations $w \in \Omega^{(l)}$. It is an optimization problem, and we solve it by the modified simulated annealing method at each level.

In the multiresolution range segmentation algorithm, we use the state information from the previous level and from the neighbors. To use the state information from the previous level, the initial state of range classes and segment indices at each level is obtained by replicating the state of the previous level:

$$(x_s^{(l)}, y_s^{(l)}) = (x_r^{(l+1)}, y_r^{(l+1)}) \quad \text{for } s \in D^{-1}(r). \quad (49)$$

Then

$$Z(y_s^{(l)}) = Z(y_r^{(l+1)}) \quad \text{for } s \in D^{-1}(r).$$

Hence, the initial condition of $w_{3,s}^{(l)}$ is obtained as

$$w_{3,s}^{(l)} = w_{3,r}^{(l+1)} \quad \text{for } s \in D^{-1}(r). \quad (50)$$

The $w_{1,s}^{(l)}$ and $w_{2,s}^{(l)}$ values are to be calculated from $w_{3,s}^{(l)}$ and the coordinate value of site s .

In standard simulated annealing for optimization, the state of a site undergoes a random change at each epoch. If there are M segments and K range classes, there are MK possible states for each epoch. To use the state information of the neighbors, the state of each site is to be changed to only one neighbor state at each epoch in the modified simulated annealing. For site $s, (x_s, y_s)$ can be changed to only one of (x_t, y_t) with $t \in \mathcal{G}_s$.

The 3-D MRS algorithm can be summarized as follows.

- 1) Determine the coarsest resolution level $l_{\max}$ and the finest resolution level $l_{\min}$.
- 2) Compute $f_{s,x}^{(l)}$ for the levels $l \in \{l_{\min}, \dots, l_{\max}\}$.
- 3) Perform the range classification at level $l_{\max}$.
- 4) Perform the merging process at level $l_{\max}$.
- 5) Perform the 3-D multiresolution range segmentation at level $l_{\max}$. Set $l = l_{\max}$.
- 6) Compute an initial state for $(\hat{x}^{(l-1)}, \hat{y}^{(l-1)})$ and $\hat{w}^{(l-1)}$ from $(\hat{x}^{(l)}, \hat{y}^{(l)})$, and $\hat{w}^{(l)}$ for each block. set $l = l - 1$.
- 7) Compute $(\hat{x}^{(l)}, \hat{y}^{(l)})$ through the minimization of (44) by the modified simulated annealing method at level (l) . If $l = l_{\min}$, stop. Otherwise, return to 6).

VII. EXPERIMENTAL RESULTS

The range segmentation method described in this paper was implemented using a camera system named Texas Active Vision Testbed (TAVT). The TAVT was built for active vision research using two cameras, and is described in [34].

Since the depth-from-focus method uses single camera, we use one of these two cameras for image acquisition. The image acquisition hardware employs Panasonic WV-CD 50 CCD camera with a nominal pixel resolution of 480×512 pixels. The RS-170 analog video signal leaving the camera is digitized using a Databcube Digimax framegrabber with an acquisition rate of 1/30 s for a full video frame. The lens used in this research is the Nikon SLR grade lens. The focal length F of the lens is 35 mm. The experiments were performed using C programming language on a Sun Workstation.

We experimented with this range segmentation method on several scenes containing multiple depth ranges. For each scene, we use an image sequence with eight different image plane distances. These images are labeled as $I_1, I_2, \dots, I_8$.

We first make the images into blocks. In these experiments, we use 32×32 blocks. In other words, we use level 5 as the coarsest resolution level. The criterion function values are computed in each block of each image by (9). The threshold value T_h in (9) is determined experimentally as a small value to reduce the noise effects, and the same value is used in all the experiments.

Fig. 1 shows two images of an image sequence with eight different focus positions. This scene contains multiple objects with multiple depth ranges. Fig. 3(a) represents the initial

Fig. 3. (a) Range quantization using focus cues. (b) Range classification result. (c) Interpolated range values. (d) 3-D display of the interpolated range values.

range classification through the range quantization using focus cues as (16). There are some range classification errors in regions that have small high-frequency content such as in homogeneous regions. Fig. 3(b) shows the range classification result. In Fig. 3(a) and (b), each region represented by each distinct gray level corresponds to one range class. Fig. 3(c) represents the interpolated range values by the cubic spline interpolation method. For blocks that are not focus measurable, we assigned the average value of the range values of the neighborhood having the same range class value. Fig. 3(d) represents the 3-D display of the 3-D vectors obtained from the interpolated ranges in Fig. 3(c). In Fig. 3(d), the arrow represents the viewing direction of the camera to the 3-D space.

Fig. 4(a) shows the 3-D display of the initial range segmentation from the range classification result. Each segment is displayed by different symbols. Fig. 4(b) shows the initial range segmentation result displayed on I_3 . Each segment is a connected region in images having the same range class values. The object at the right side is located in two range classes in the range classification and is composed of four segments in the initial range segmentation. Fig. 4(c) is the 3-D display of the range segmentation result after the merging process. Fig. 4(d) shows the range segmentation result displayed on

I_3 . In Fig. 4(c), we can see how the objects are located in the WCS and segmented into different objects or different depth ranges. This gives a description of the 3-D structure of a scene. Fig. 4(d) shows that objects in different depth range are segmented into different segments. Note that the object at the right side, which is located in two range classes in the range classification and is composed of four segments in the initial range segmentation, is merged into one object in the merging process. This result is obtained at a coarse resolution using 32×32 blocks.

To refine the segmentation into finer resolutions, we perform the 3-D MRS described in Section VI. In the 3-D MRS, we set $l_{\max} = 5$ and $l_{\min} = 2$. Fig. 5(a) represents the 3-D display of the final 3-D MRS result at level 2. In the 3-D MRS, range segmentation and 3-D reconstruction is performed simultaneously. Fig. 5(b) shows the corresponding 3-D MRS result at level 2 displayed on I_3 .

In this result, there are some errors in the computed boundary shapes. There are two reasons for these errors. These are the insufficiency of the amount of high-frequency content in some locations (that are not focus measurable) and the geometrical distortion arising in defocused images.

High-frequency content is the most important information for range classification and for range segmentation using

Fig. 4. (a) Three-dimensional display of the initial range segmentation from the range classification result. (b) Initial range segmentation displayed on I_3 . (c) Three-dimensional display of the range segmentation result after the merging process. (d) Range segmentation result displayed on I_3 .

Fig. 5. (a) Three-dimensional display of final 3-D MRS result at level 2. (b) Final 3-D MRS result at level 2 displayed on I_3 .

focus information. High-frequency content contributes to the criterion function values for focus measure. The criterion function values are used in the range quantization, in the range classification and in the 3-D MRS steps. If a region is homogeneous and does not contain a sufficient amount of high frequency content, then this region can create errors in the range quantization, in the range classification and in the 3-D MRS steps. If this region is surrounded by regions having the same range classes, then the error in the range quantization would be corrected in the range classification step, because the energy functional defined by the MRF model contains the range class information of the neighborhood. However, if this region is located in the boundary area between different range classes, then the error in the range quantization may not be corrected in the range classification. Similarly, if a region does not contain a sufficient amount of high-frequency content and is located in the boundary area between different segments with different ranges, then this region might be segmented incorrectly in the 3-D MRS. This effect becomes more severe as the region size becomes smaller, i.e., as the resolution level becomes lower. Once an error has occurred in the 3-D MRS at a high level, then this error would be propagated to the corresponding regions at lower levels. In Fig. 3(b), most errors in the range quantization are corrected in the range classification except at one block in the middle. This block corresponds to the “table” below the “bunny” having the same range class as

Fig. 6. (a) One image of an image sequence with eight different focus positions. (b) Range quantization using focus cues. (c) Range classification result. (d) 3-D display of the initial range segmentation. (e) Initial range segmentation displayed on I_3 . (f) Range segmentation result after the merging process displayed on I_3 . the background in Fig. 1. This block does not contain sufficient high-frequency content and is located in the boundary area of different range classes. The region corresponding to this block is also incorrectly segmented in the 3-D MRS. Because this region contains small high-frequency content and is located on the boundary area of different segments with different depth ranges, errors are propagated to the following lower levels.

Fig. 6(a) shows one image of an image sequence taken with eight different focus positions. Fig. 6(b) represents the initial range classification through the range quantization process. There are some classification errors in regions that have little high-frequency content such as in homogeneous regions. Fig. 6(c) shows the range classification result. Note

that the object at the lower left side is located in four range classes. Fig. 6(d) shows the 3-D display of the initial range segmentation from the range classification result. Each segment is displayed by different symbols. Fig. 6(e) shows the initial range segmentation result displayed on I_3 . The object at the lower left side is composed of four segments. Fig. 6(f) shows the range segmentation result after the merging process displayed on I_3 . Note that the object at the lower left side, which is located in four range classes in the range classification, is merged into one object in the 3-D merging process. Fig. 6(g) represents the 3-D display of the final 3-D MRS result at level 2. Fig. 6(h) shows the corresponding 3-D MRS result at level 2 displayed on I_3 .

Fig. 7. (a) One image of an image sequence with eight different focus positions. (b) Range classification result. (c) 3-D display of the initial range segmentation. (d) Initial range segmentation. (e) Range segmentation result after the merging process. (f) Final 3-D MRS result at level 2.

There are geometrical distortions in defocused images [6], [13]. The geometrical distortions are due to the magnification effect of a lens system. Because of geometrical distortion, point locations in images for the same object point in the WCS may not be the same if the image plane distances are different. Hence image features are shifted in images with different image plane distances by the geometrical distortion. The use of larger windows or larger regions for focus measure would reduce the geometrical distortion problem at the cost of decreased spatial resolution [10]. In Fig. 6(h), the boundary shape between the upper part of the radio and the background looks a little shifted. The boundary is slightly shifted to the inside of the radio in most areas, and the boundary is located at the correct position in just a few places. These errors are due to the geometrical distortion. Fig. 6(i) shows the range segmentation result at level 2 displayed on I_7 . In Fig. 6(i), the boundary is located at the correct position in most places, and is slightly shifted to the outside of the radio in a few spots, contrary to the case in Fig. 6(h).

Fig. 7 shows another experimental result. Fig. 7(a) shows one image, I_3 , of an image sequence ($I_1, I_2, \dots, I_8$) with different focus positions. In this scene, the object at the left side is located in multiple range classes as in Fig. 6. Fig. 7(b) shows the range classification result. Fig. 7(c) shows the 3-D display of the initial range segmentation from the range

classification result. Each segment is displayed by different symbols. Fig. 7(d) shows the initial range segmentation result displayed on I_3 . The object at the left side is segmented into eight segments in the initial range segmentation. This scene has a more complex structure for the merging process than that of Fig. 6. Fig. 7(e) shows the range segmentation result after the merging process displayed on I_3 . Note that the object at the left side, which is located in four range classes in the range classification and is composed of eight segments in the initial range segmentation, is merged into one object in the 3-D merging process. Fig. 7(f) represents the final 3-D MRS result at level 2 displayed on I_3 . There are some boundary errors between the right side of the radio and the background. The boundary is slightly shifted relative to the background. These errors occur because there is not sufficient amount of high-frequency content in this local region.

Fig. 8 shows another result. In this scene, we use ten images with different focus positions. Fig. 8(a) shows one image, I_3 , of the image sequence with different focus positions. Fig. 8(b) shows the initial range segmentation result after the range classification displayed on I_3 . The object at the bottom is composed of four segments. Fig. 8(c) represents the final 3-D MRS result at level 2 displayed on I_3 .

In these experimental results, the 3-D MRS method effectively segments a scene into different depth ranges or different

Fig. 8. (a) One image of an image sequence with ten different focus positions. (b) Initial range segmentation. (c) Final 3-D MRS result at level 2.

Fig. 9. (a) One image of an image sequence with eight different focus positions. (b) Final 3-D MRS result at level 2.

objects. The range segmentation provides a rich description of the 3-D structure of a scene.

Now we present an example of depth measurement. Fig. 9(a) shows one of the images with different focus positions. In this example, we use eight images with different focus positions. The object displayed in the bottom in images in Fig. 9(a) is located at about 100 cm from the camera. The background is located at about 367 cm from the camera.

Fig. 9(b) shows the final 3-D MRS result at level 2. The object in the front in Fig. 9(b) is mapped between 90 and

Fig. 10. Graph of the look-up table as depth versus range class value.

110 cm. The background in Fig. 9(b) is mapped between 304 and 367 cm. The background that is located at larger distance results in larger errors in depth measurement. Overall, the range segmentation method provides coarse depth estimates of objects in the scene with some errors.

The reasons for these errors in depth measurement are as follows.

- *Small number of images with different image plane distances:* We use eight images with different image plane distances. To obtain a more accurate depth measurement, we need to use larger number of images with different focus positions.
- *Calibration problem:* A look-up table is used to obtain depth from the range class values. Fig. 10 shows the graph of the look-up table as depth versus range class value. There are eight quantized range class values corresponding to eight images. There are nine interpolated range class values between quantized range class values. Hence there are 71 interpolated range class values in the look-up table. To build the look-up table, we first measure distances at about ten locations with different depth and find the corresponding image plane locations, i.e.,

the corresponding interpolated range class values. The look-up table was built by interpolating these measured depth points through the range class values. This look-up table may contain some errors and this is the calibration problem. If we can obtain more accurate look-up table of the lens system, then we will obtain more accurate depth measurement by the range segmentation method.

- *Nonlinear relationship between depth and range class value:* In Fig. 10, there is a nonlinear relationship between depth and range class value. As the range class value becomes larger, the interval between depth becomes larger and the error in depth measurement becomes larger. In the result, the object in the front is located at between 90 and 110 cm corresponding to 4.5 and 5.0 in range class values, and the background is located at between 304 and 367 cm corresponding to 7.0 and 7.3 in range class values. When the range class value is large, small errors in range class value result in large errors in depth measurement.

VIII. CONCLUSION

This paper presents a new range segmentation paradigm using focus cues. In range segmentation, a scene is segmented into 3-D regions representing connected object surfaces with different depth ranges, producing a rich description of the 3-D structure of the scene. The range segmentation is composed of three steps: a range classification, a merging process, and a 3-D multiresolution range segmentation.

First, range classification is performed to obtain quantized range estimates. The range classification is performed by combining two paradigms: focus cues and Bayesian estimation. To combine these two paradigms, a combined energy functional from the criterion function values for focus measurement and from the Gibbs distribution of the class field is defined. The range classification results in quantized range estimates, and it also provides an initial range segmentation.

Second, a merging process is performed to merge initial segments from the range classification result. In the merging process, GMRF's are used to model the fields of 3-D vectors of a segment. The pseudolikelihood ratio between segments is defined from the GMRF's, and is used as a merging criterion. After the merging process, an object that is located in multiple range classes and is composed of multiple segments in the initial range classes and is composed of multiple segments in the initial range segmentation, is merged into one object. The merging process gives a 3-D range segmentation at the coarsest resolution.

Third, 3-D multiresolution range segmentation (3-D MRS) is performed to refine the range segmentation into finer resolutions. In the 3-D MRS, multiresolution MRF's are used to model the fields of segment indices, range classes, and the 3-D vectors in segments. Using the MRF-Gibbs equivalence, energy functionals from segment indices and the 3-D vectors are defined. Also, an energy functional from the criterion function values is defined. A combined energy functional is defined as the weighted summation of these energy functionals. The combined energy functional includes information from the criterion function values, the segment indices and the 3-D vectors. To

create a multiresolution framework, the energy functionals are defined over multiple resolutions. The proposed 3-D MRS algorithm first performs range segmentation at the coarsest resolution and proceeds progressively to finer resolutions.

This paper presents a complete procedure to obtain high-resolution range segmentation given a finite number of images taken with different focus positions. The proposed range segmentation method does not require initial depth estimates and is applicable for scenes containing multiple objects with multiple depth ranges. The range segmentation provides a rich description of the 3-D structure of a scene.

The limitations of the range segmentation method in this paper are as follows.

- *Dependence on high-frequency content:* If a scene does not contain enough high-frequency content in most part of the scene, then the range segmentation method may not work.
- *Depth quantization effect:* If two disconnected objects are located in the same depth range and are spatially adjacent in images, then the range segmentation method cannot separate them into different objects.
- *Scene should be static:* If either any object or the camera is moving, then the range segmentation method may not work correctly because of registration problem.
- *Spatial resolution and object size:* If any object in the scene is smaller than one image block at the coarsest resolution, then the object may be lost in the range segmentation steps.

To overcome these limitations, some future researches could be performed as follows.

First, some research can be performed to overcome the dependence on high-frequency content. The integration with other depth cues (e.g., stereo) can be explored. Also, the integration with other features such as intensity, edges, and textures can be performed.

Second, some research can be performed to reduce the depth quantization effect. One simple way is just taking a larger number of images with different image plane distances. Another way is to take images using an active vision strategy. If an object is located in a certain depth range (this information can be provided after the range classification step), then we can control the focus position of the lens and take more images with smaller interval of image plane distances. In this way, we can reduce the depth quantization effect.

Third, if a camera system is developed to take images with different focus positions simultaneously, then the range segmentation method can be applied to the cases of moving objects or moving cameras.

There are interesting issues remaining regarding the more complete and efficient implementation for range segmentation. We present three steps for range segmentation: range classification, merging process, and 3-D MRS. There may be many other more complete and efficient ways for each of these steps, which can be explored in future research. For example, a statistical method is employed using the MRF model for each of these steps. To make the algorithm perform faster, some deterministic methods can be explored.

Changhoon Yim (S'93–M'96) received the B.Eng. degree from the Department of Control and Instrumentation, Seoul National University, Seoul, Korea, in 1986, the M.S. degree in electrical engineering from Korea Advanced Institute of Science and Technology, Seoul, in 1988, and the Ph.D. degree in electrical engineering from The University of Texas at Austin, Austin, TX, in 1996.

From 1988 to 1991, he was a Research Engineer working on HDTV at Korean Broadcasting System, Seoul. During the summer of 1993, he was an intern working on image processing at Tracor Applied Sciences, Austin. From 1994 to 1995, he held a part-time research fellowship at Schlumberger Austin Research, Austin, working on array signal processing. Since 1996, he has been a Member of Technical Staff in the Compression Systems Group, HDTV and Multimedia Division, Sarnoff Corporation, Princeton, NJ. His research interests include video and image processing, video compression, 3-D segmentation, compressed-domain processing, digital TV, and multimedia.

Alan C. Bovik (S'80–M'81–SM'89–F'96) was born in Kirkwood, MO, on June 25, 1958. He received the B.S. degree in computer engineering in 1980, and the M.S. and Ph.D. degrees in electrical and computer engineering in 1982 and 1984, respectively, all from the University of Illinois, Urbana-Champaign.

He is currently the General Dynamics Endowed Fellow and Professor in the Department of Electrical and Computer Engineering, the Department of Computer Sciences, and the Biomedical Engineering Program, The University of Texas at Austin, where he is also the Associate Director of the Center for Vision and Image Sciences. During the spring of 1992, he held a visiting position in the Division of Applied Sciences, Harvard University, Cambridge, MA. He is a registered Professional Engineer in the State of Texas and is a frequent consultant to industry and academic institutions. His current research interests include digital video, image processing, computer vision, wavelets, 3-D microscopy, and computational aspects of biological visual perception. He has published over 250 technical articles in these areas. He holds U.S. patents for the image and video compression algorithms VPIC and VPISC.

Dr. Bovik is a winner of the University of Texas Engineering Foundation Halliburton Award and a two-time Honorable Mention winner of the international Pattern Recognition Society Award for Outstanding Contribution (1988 and 1993). He has been involved in numerous professional society activities, including Board of Governors, IEEE Signal Processing Society (1996–present); Editor-in-Chief, IEEE TRANSACTIONS ON IMAGE PROCESSING (1996–present); Editorial Board, *Pattern Analysis and Applications* (1997–present); Area Editor, *Graphical Models and Image Processing* (1995–present); Associate Editor, IEEE SIGNAL PROCESSING LETTERS (1993–1995); Associate Editor (IEEE TRANSACTIONS ON SIGNAL PROCESSING) (1989–1993); Editorial Board, *Pattern Recognition* (1988–present); and Editorial Board, *Journal of Visual Communication and Image Representation* (1992–1995). He has been on the Steering Committee for IEEE TRANSACTIONS ON IMAGE PROCESSING (1991–1995); and Founding General Chairman of the *First IEEE International Conference on Image Processing*, Austin, TX, November 1994.
